Chapter 1

Introduction

1.1 Technical Context

1.2 Objectives and Contributions

1.3 Outline of Report

Chapter 2

Background

2.1 Clinical Context

This project will have its foundation for experimentation in a dataset provided by the Royal Marsden Hospital. The real-world clinical dataset segments key anatomies and tumours that aid in radiotherapy planning for females with cervical cancer. It has yet to gain exposure to the widespread segmentation challenges and has uncommon and limited segmentation patterns. This dataset will act as the pillar for justifying the success of the transferability of knowledge between medical domains.

In this section, we discuss the clinical context behind cervical cancer in the population, the Hospital’s pipeline for segmenting patients in preparation for radiotherapy treatment, and the Hospital’s motivation for recruiting an AI tool to assist in its treatment pipeline.

2.1.1 Cervical Cancer

Cancer is a burden around the globe that has been a driver for almost one-sixth of the world’s mortality in 2022 [1]. In females, cervical cancer makes up 25 countries’ leading causes of cancer death, following breast cancer in 157 in 2022 [1]. Furthermore, an estimated 1 million maternal orphans who lose their mothers to cancer suffer long-term disadvantages in health and education [2]. Thankfully, cancer screening services provided by hospitals around Europe have been shown to decrease incidence and mortality rates of cervical cancer in women over the recent years [1], which inspires further complete clinical understanding of the disease. This motivation and the potential to pair with quality improvements offered by medical imaging models drive this research project to explore transfer knowledge in this field.

2.1.2 Radiotherapy Treatment

A mechanism available for cancer treatment involves radiation therapy. High beams of radiation energy are tuned to hone in to target cancerous cells in a clinically defined ‘target area’. The cells killed by the energy experience interphase or proliferative death depending on the cell cycle stage. Death occurs when the damage to genetic material within the cell prevents it from dividing, or the cell’s accumulation of genetic aberrations leads to a “mitotic catastrophe” [3]. In Europe, radiotherapy treatment was used on average for 70% of cases, with a curative rate of 40% [4, 5].

This death is characteristic of any cell subjected to high energy beams, placing much responsibility on the Oncologist to deliver an accurate treatment area so that healthy cells are unaffected; any adverse alteration of an organ's standard functionality may cause grave implications for the already compromised patient. Therefore, the precise and complex nature of the task is estimated to take oncologists 90-120 mins to delineate target areas for radiotherapy [6].

This time-consuming endeavour is never favourable for a patient already in a dangerous situation. For mid-low-income countries, where this may not be an available resource, this leaves them with a death rate 18 times that of a higher-income country [7].

2.1.3 CT modality

Development in high-resolution and high-contrast X-ray imaging (CT scans) machines has further incentivised radiotherapy treatment due to its noninvasive nature and ability to view patients' internal organs. X-ray devices rotate around a specified body part, and computer-generated cross-sectional images are produced [8]. Whilst the scanner rotates, the patient's table slowly moves up and down inside the tube to produce different cross-section images. The images show damaged and surrounding soft tissue, allowing physicians to propose clinical target volumes more accurately.

Hounsfield Units

(a) Muscle Window (35, 55) [9] (b) Cancellous Bone Window (300, 400) [10] (c) Fat Window (-120, -90) [9]

Figure 2.1: Coronal view the same image slice of a CT image, with different window cropping (Patient id: 49, slice 251, axis 1)

The operator or physician decides the granularity or image slice thickness, which ranges from 1mm to 10mm. Therefore, the precision along each axis creates a cube, or voxel, representing the value on a grid in three-dimensional space. The voxel values are measured in Hounsfield Units (HU) [11].

Contrary to natural images, where pixel values vary from 0 to 255 in 3 channels representing Red, Blue and Green, the Hounsfield scale is a quantitative scale describing radiodensity. The image intensity reflects tissue type; each voxel intensity refers to a specific tissue composition. The positive values result from more dense tissue with greater X-ray beam absorption, and negative values are less dense tissue with less X-ray beam absorption [12].

Therefore, because the HU scale is relative, different windows may be taken for a CT scan to highlight different tissues. Those voxels within the window will likely be tissues of a specific classification. For example, as shown in Figure 2.1, we display three such windows: muscle, cancellous bone and fat.

2.1.4 Radiotherapy Planning

👉 Perhaps, include a graph to visualise target volumes visually

Oncologist use the CT scans to draw clinical volumes by combining their knowledge about the particular cancer to determine target structures, organs-at-risk structures, and areas where the cancer will likely spread to [13].

The first area is the macroscopic delineated area of the visible tumour area. This Gross Target Volume (GTV) has a high probability of containing the tumour. Secondly, the Clinical Target Volume (CTV) is derived to account for potential microscopic spread. The CTV will be an area at least as big as the GTV with an optional margin surrounding it containing a 'rind' of non-zero probability of tumour spread. Lastly, the Primary Target Volume (PTV) contains residual geometric uncertainties and safety margins surrounding the CTV, ensuring the radiotherapy dose gets delivered to the CTV [14, 15, 16, 17]. The PTV is a necessary extension of the CTV since geometric uncertainties are impossible and not advised to eliminate; after all, static scans are only estimations, subject to short-term organ misalignment, relative movement between structures of reference and tumours, partial volume effects and skewed anisotropic resolution [18].

In parallel, the Oncologist constantly considers critical healthy tissue structures that need to be preserved during irradiation. These are referred to as organs-at-risk (ORs). In some specific circumstances, adding a margin analogous to the PTV margin around an OR is necessary to ensure that the organ cannot receive a higher-than-safe dose; this gives a planning organ at risk volume [15].

2.1.5 International Guidelines

The final volumes have no internationally agreed-upon guidelines, which leaves it up to the interpretation of the oncologists and Hospitals to use their heuristics when drawing areas. This time-consuming process has high variability, causing it to suffer significantly from inter and intra-observer variability [16].

2.1.6 Data Acquisition

The Royal Marsden Hospital provides the dataset as a set of 'Neuroimaging Informatics Technology Initiative' files (NIfTI) [8]. It is a lightweight alternative to other formats such as DICOM and eliminates ambiguity from spatial orientation information [19]. Libraries exist for handling these files, such as SimpleITK [20], which we use to read and manipulate the data in this project. The library reads, manipulates, and handles the image as a set of points in a grid occupying a physical region in space defined by the metadata to remove ambiguity from the origin, size, spacing, and so on that might vary between patient scans.

The training data provides one hundred female patients that have been diagnosed with similar types of cervical cancer. Each patient comes with seven relevant segmentation classes

which contribute to radiotherapy planning. For reproducibility, all delineated anatomies were labelled consistently by the Oncologists to improve chances that an AI model can learn cervical cancer patterns [13].

Finally, the dataset comes with ten hold-out data items, which are patients with only the raw CT scan information without labels.

2.1.7 Delineation classes

The clinicians at the Royal Marsden Hospital have provided segmentation labels for seven high-priority classes of interest. These are the Bladder, Anorectum, CTVn, CTVp, Parametrium, Uterus, and Vagina. The function of these anatomies is irrelevant to this project and is left to the reader to research further. Note that for the sake of this report, the only deviation from clinical understanding is the CTV cancerous delineations.

Organs At Risk

Figure 2.2: Views of the segmentation (in red) of the Anorectum (2.2(a)-2.2(c)) and the segmentation (in red) of the Bladder (2.2(d)-2.2(f)) of an arbitrary patient

An organ at risk is an organ that, despite being healthy, is substantially likely to be within the PTV. Any areas created around the area should actively avoid these organs because overlapping with them risks complicating treatment and compromising the health of functioning organs. The key supplied anatomies at risk are the Anorectum (Figure 2.2(a)-2.2(c)) and the Bladder (Figure 2.2(d)-2.2(f)).

CTVp

Figure 2.3: Views of a segmented (in red) CTVp of an arbitrary patient

The CTVp stands for the Primary Clinical Target Volume; see the example at Figure 2.3. This is an extension of the CTV definition (Section 2.1.4) where there may be local microscopic spread (uterus, cervix, upper vagina, primary tumour) [13]. This is the area that contains the tumour.

The CTVp is not an organ in a body but rather an area comprised of other components formed by joining other structures. The CTVp is an area defined in Equation ??.

CTVn

Figure 2.4: Views of a segmented (in red) CTVn of an arbitrary patient

The CTVn stands for Nodal Clinical Target Volume; see the example at Figure 2.4. Once again, this is an extension of the CTV definition (Section 2.1.4), with the enhanced condition that there may be microscopic spread to lymph nodes. It is drawn based on set margins around pelvic blood vessels and includes pelvic lymph nodes, common iliac lymph nodes and para-aortic lymph nodes [13].

Similarly to CTVp, this is a compound area with three groups of lymph nodes. In clinical practice, the number of these groups in the CTV varies in each patient, depending on the advanced disease. The CTVn is an area defined in Equation 2.3.

Parametrium

Figure 2.5: Views of a segmented (in red) Parametrium of an arbitrary patient

The Parametrium (or Paravagina) is the tissue surrounding the cervix/vagina - at risk of local spread; see Figure 2.5. The Parametrium is drawn as a complete structure and edited back to the level of the vagina to be included [13].

Vagina and Uterus

 Insert similar figure here

The final structures are the Vagina and Uterus, their clinical significance is to help define encapsulating structures like the CTVn (see Section 2.1.8).

2.1.8 Rules

Notation of Structures

- | | |
|--|---|
| 1. Let the Anorectum be denoted as A | 8. Let the Pelvic Lymph Node be denoted as L_p |
| 2. Let the Bladder be denoted as B | 9. Let the Common Iliac Lymph Node be denoted as L_i |
| 3. Let the Cervix be denoted with C | 10. Let the Para-aortic Lymph Node be denoted as L_{pa} |
| 4. Let the CTVn be denoted with C_n | 11. Let the Parametrium be denoted with P |
| 5. Let the CTVp be denoted with C_p | 12. Let the Uterus be denoted with U |
| 6. Let the GTVp be denoted with G_p | 13. Let the Vagina be denoted with V |
| 7. Let the GTVn be denoted with G_n | |

Relationship between Structures

1. If we want to talk about a specific patient, we should use the super-script notation to differentiate patients, e.g., B^i for the Bladder of patient i .
2. Let the overlap of two structures be denoted by the set intersect symbol \cap .

3. Let the joint area of two structures be denoted by the set union symbol \cup .

The top seven priority structures have been selected to identify and plan an area where radiotherapy should be used. With these structures, there are rules that the clinicians have outlined, they are quoted for clarification (these structures only refer to each independent patient):

1. There should be no overlap between the CTVn, CTVp or Anorectum.

$$\forall i, j \in \{C_n, C_p, A\} \text{ with } i \neq j, i \cap j = \emptyset \quad (2.1)$$

2. The Parametrium may overlap with all of the other structures.

$$\forall i \in S, \quad P \cap S_i \neq \emptyset \vee P \cap S_i = \emptyset \quad (2.2)$$

3. The Bladder may overlap with the CTVn.

$$B \cap C_n \neq \emptyset \vee B \cap C_n = \emptyset \quad (2.3)$$

4. The CTVp is defined as a compound structure containing:

$$C_p = \overbrace{C \cup G_p}^{\text{High Risk CTV}} \cup U \cup V \quad (2.4)$$

However, since we are never explicitly provided with the segmentation maps for the Cervix C and the GTVp G_p , we cannot use as strong of a definition as above. Instead, we operate on the assumption that the union of the Uterus and Vagina is at least as big as the CTVp.

$$U \cup V \subseteq C_p \quad (2.5)$$

5. The CTVn is defined as a compound structure containing:

$$C_n = G_n \cup L_i \cup L_p + L_{pa} \quad (2.6)$$

Similarly, we are not provided segmentations for these areas, therefore, operating under no clinical knoweldge apart from the provided, cannot make any claims as to the composition of the CTVn.

2.1.9 Motivation in AI

The key objective of models trained for delineating target structures is to see if an AI model can learn cervical cancer CTV pattern detection. The decision is complex as clinicians use information beyond the CT-imaging modality, such as how far along the tumour has progressed, and other clinical intuition to make proper judgements about the CTV volumes. Therefore, with this information missing from AI models, it is likely to misjudge target volumes, and a clinician will have to select which components of the CTV are required. However, a clinician will likely benefit from the time saved and improved consistency with the planning process if a trained model can produce the substructures required within the CTV that a clinician can review [13].

2.2.5 SAM

2.3 Evaluation Metrics

Calculating the difference between the provided labelled data would be one way to determine if a contour can be used in a clinical context. However, we have different ways to evaluate this measure in a delineation context.

If we were attempting to fit a model onto a line in 2D space, the performance of our model would be the total minimum distance between each point and the prediction. Our objective would be to drive the model's distance metric as close to 0 without overfitting. Here, the points act as a 'ground truth', alternatively referred to as the gold standard, which represents the actual measured value.

The reasoning above extends to 3D and 2D in a segmentation context with variants to measure other quantities, like the minimum distance between prediction and truth or the extent of volume overlap between the two. These are examples of geometric measures, which Mackay et al. has found to be the most popular measure in segmentation tasks [21].

2.3.1 Classification Based

Assesses if voxels within and outside the auto-contour have been correctly labelled [21]. To begin, we define 'positive' to mean that the voxel selected is indeed in need of radiotherapy treatment, and 'negative' to mean that the voxel is classified as healthy.

A standard measure of classification is accuracy. It measures the total amount of correct predictions vs the total predictions it made. However, this measure alone isn't enough to fully capture the bias of a model because it doesn't tell you the full story with class-imbalanced data when there isn't an even number between positive and negative labels.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

Better measures are Precision and Recall scores. The Precision (also known as the Positive Predictive Value [22]) measures the proportion of predictions that were successfully correct. The Recall (also known as True Positive Rate [22]), on the other hand, "measures the portion of positive voxels in the ground truth that are also identified as positive by the segmentation being evaluated".

$$\text{Precision} = \frac{TP}{TP + FP}, \quad \text{Recall} = \frac{TP}{TP + FN}$$

2.3.2 Spatial Overlap Based

Similarly to Classification Based metrics in Section 2.3.1, an Overlap Based metric measures the extent of overlap between an auto-contour and a reference structure [21].

The scores above can be combined into a more general score F_β to give

$$F_\beta = (1 + \beta^2) \cdot \frac{\text{Precision} \cdot \text{Recall}}{\beta^2 \cdot \text{Precision} + \text{Recall}}$$

A specific case of this equation with $\beta = 1$ is mathematically equivalent to the DICE Similarity Coefficient which was found to be the most popular evaluation metric amongst 2021 studies [21, 22, 23].

$$F_1 = \text{DICE} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} = \frac{2 \cdot TP}{2TP + FP + FN} = \frac{2|S_g \cap S_p|}{|S_g| + |S_p|}$$

Where S_g is the ground truth segmentation and S_p is the predicted segmentation. From this relationship, the DICE score has found popularity in image segmentation for similar reasons that the F_1 score has found its popularity classical machine learning; it is able to provide a fair result for imbalanced datasets. This mentality is applicable in our scenario because a tumour will make up very little of the total volume of the domain space. This can be extended to a Volumetric DSC by considering the above in all 3-dimensions [24].

Another popular related evaluation method is the Jaccard Index, which measures the intersection over the union of two sets:

$$\text{JAC} = \frac{TP}{TP + FP + FN} = \frac{|S_g \cap S_p|}{|S_g \cup S_p|} \iff \frac{\text{DICE}}{2 - \text{DICE}}$$

Since the numerator for the Jaccard Index is smaller (since we avoid the issue of counting the intersecting sections twice) the JAC is always larger than the DICE score.

2.3.3 Surface Based

Also commonly known as Boundary-Distance-Based Methods [25] compares the distance between two structure surfaces. These can be either maximum distance, average distance or distance at a set percentile of ordered distances [22].

A common example is the Hausdorff Distance. Here, a directed distance metric is defined as the maximum distance from a point in the first set to a nearest point in the other between two individual voxels [25]. Therefore, the better the HD metric, the smaller the value it returns. Here, the distance is taken by some norm, typically Euclidian distance.

$$\text{HD}(A, B) = \max(h(A, B), h(B, A)), \quad \text{and directed } h(A, B) = \max_{a \in A} \min_{b \in B} \|a - b\|$$

The HD is generally sensitive to outliers. Because noise and outliers are common in medical segmentations, it is not recommended to use the HD directly [25]. Therefore, we can calculate the average directed Hausdorff Distance.

2.3.4 Volume Based

Volume-based metrics consider only the volume of the segmentation [26, 21, 25]. However, due to its poor spatial descriptions it is more commonly used jointly with other metrics.

$$\text{Relative Volume Difference (RVD)} = \left| \frac{|S_g| - |S_p|}{|S_g|} \right|$$

2.3.5 Evaluation

All these methods can be advantageous in some places rather than other. We can begin to list off some challenging scenarios to decide which segmentation is the best.

Figure 2.6: Figure from [25] illustrating cases of segmentation to aid with explanation of setbacks of certain evaluation metrics

- Classification Based (Section 2.3.1) and Spatial Overlap Based (Section 2.3.2) are similar; they are concerned with the number of correctly classified or misclassified voxels without taking into account their spatial distribution. Here, Figure 2.6(a) and Figure 2.6(c) would achieve similar results despite Figure 2.6(a) being locally bound to a better area.
- With Hausdorff Distance (Section 2.3.3) output segmentations generated by Figure 2.6(d) and Figure 2.6(e) will result in the same score, which is not favorable in a radiotherapy planning environment where an organ-at-risk is involved.
- Figure 2.6(b) would score flawlessly when using volumetric score estimation, however, it doesn't take into account spatial placement, which makes this measurement rather poor when used individually.

2.3.6 Estimated Editing Based

👉 This is a quotation from this paper, [23], however, it is referencing a paper of its own. Shall I reference the original paper or are 'linked' references OK?

It is difficult to select a measurement which can reflect a clinician's acceptability score. A study found that there was a lack of correlation between a geometric index and expert evaluation, with the JAC score having a 13% False Positive Rate. The conclusion of the study summarised that scores such as JSC and volumetric DSC, "provide limited clinical context and correlation with clinical or dosimetric quality" [23].

Surface DSC

The study at [23] helped drive an initiative to combine aspects of Surface Based evaluation (Section 2.3.3) and Spatial Overlap Based evaluation (Section 2.3.2) into a Surface DICE. This assesses the specified tolerance instead of the overlap of the two volumes.

Figure 2.7: Taken from [27]. Illustrates the computation of the surface DICE, where the continuous line is the predicted surface and the dashed line is the ground truth. The black arrows show the maximum deviation tolerated without penalty; therefore, in pink is the unacceptable deviations and green otherwise.

We can formulate the Surface DSC score in a mathematical definition [23].

$$\text{Surface DSC} = \frac{|S_p \cap B_{g,\tau}| + |S_g \cap B_{p,\tau}|}{|S_p| + |S_g|}$$

Which provides a measure of the agreement between just the surfaces of two structures above a clinically determined tolerance parameter, τ . Here, $B_{p,\tau}$ represents the boundary region of the predicted surface within a maximum margin of deviation τ and similarly for $B_{g,\tau}$ for the ground truth.

Added Path Length

In a similar spirit, the APL was proposed as a score to predict “the path length of a contour that has to be added” [24]. This is achieved similarly by considering the number of added voxels required between the prediction and the gold standard with no regard to tolerance as a pose to Surface DSC (Section 2.3.6)

👉 For future reference, *stack overflow discussion*
Implementation of surface DSC and APL: *source code*

2.3.7 Summary

This is why we settle at the Surface DSC (Section 2.3.6) which prioritizes deviation along boundary to a certain degree while measuring the fraction of the surface that needs to be redrawn, thus favouring a more conservative prediction of Figure 2.6(d) instead of (e).

For the purpose of this project, we shall select a evaluation measurement which is more bias towards conservative boundary estimates to not touch the organs at risk. This choice was

in-part influenced by the clinician's review pipeline; it would be easier to correct Figure 2.6(d) instead of Figure 2.6(e) because correcting the latter would likely take a considerable amount of time as it would require redrawing almost all of the boundary, whereas the former could be corrected much faster [27].

Chapter 6

Conclusion

Transfer works!

Chapter 7

Ethics

The lack of effort to protect the identities and confidentiality of patients during research projects may result in “stigma, embarrassment, and discrimination” [28] if the data is misused. This project involves the intimate and personal information of many female patients whose privacy must be protected before research occurs.

7.1 Patient disclosures

Researchers may collaborate with third parties, such as Imperial College London, by providing anonymised data that third parties cannot reverse-engineer to identify the patient. The collaborating hospital, The Royal Marsden Hospital, does not require “explicit consent” for sharing collected clinical data with outside entities as long as the patient is made aware of the ways their “de-identified/anonymised” data may be used. [29]. Imperial College’s Medical Imaging team also arranges formalities, such as acting as “ethical data stewards” [30].

The MIRA team acts as responsible data stewards by storing anonymised data within a folder on the college network. They received all provided data in the NIfTI file format, which discloses no personally identifiable information, as defined by the GOV website [31]. Specific access rights limit data availability in this folder, ensuring security measures. Moreover, taking the data outside this folder reduces individual patient risk through the exchange of de-identified data.

Without such disclosure, anonymisation, and a security guarantee of the data, patients may be reluctant to provide candid and complete disclosures of their sensitive information, even to physicians, which may prevent a complete diagnosis if their data is not maintained anonymously.

7.2 Using the tool

The applications of this tool bode well in the healthcare ecosystem as the community slowly accepts the involvement of AI-powered medical tools. Radiology is one application that has been most welcoming of the new technological advances as there is potential for substantial aid by reducing manual labour, increasing precision and freeing up the primary care physician’s time [32].

However, it is too early to take the results of the medical tool as gospel. For current cervical radiotherapy delineation tools, only 90% of the output is acceptable for clinical use [33].

Therefore, The remainder can potentially cause more harm than good if not checked properly. For example, the overlap of a PTV with an organ-at-risk may invoke a cascade of adverse effects for the patient. The remaining 10% of outputs may score incorrectly because the model uses a single modality, but physicians may base their final judgement on a multivariate analysis. Therefore, clinicians should use the tool as a second opinion rather than a primary source of information. Otherwise, an ethical dilemma of establishing the responsible party for incorrect decisions made by DL tools should also be determined [34].

Clinicians can fall into the trap of automation bias as AI becomes more commonplace in clinical environments [35]. However, many models of this age codify the existing bias in common cases, which often will fail those patients who do not fit the majority's expectations. Therefore, before integrating tools into workflows, a committee must establish the degree of supervision required from physicians if this tool is to be used in practice. Currently, oncologists will be required to reverse-engineer the 'black box' results to verify why a decision has been made.
